(Received 27 February 2019; published 21 May 2019)

We study spin eigenexcitation of a skyrmion in a collinear uniaxial antiferromagnet by means of analytical and numerical methods. We found a discrete spectrum of modes which are localized on the skyrmion. Based on a qualitatively different dependence of the mode eigenfrequencies on the skyrmion radius $R_0$, we divided all localized modes into two branches. Modes of the low-frequency branch are analogous to the localized magnon modes of a ferromagnetic skyrmion, their frequencies scale as $R_0^{-2}$ for the large radius skyrmions, while the modes of the high-frequency branch have no direct ferromagnetic counterpart and do not demonstrate the significant radius dependence and are compactly situated at the magnon continuum. All the modes, except the radially symmetrical one, are doubly degenerated with respect to the sense of rotation around the skyrmion center: clockwise or counterclockwise. An out-of-plane magnetic field removes the degeneracy (for all modes except translational), resulting in a frequency splitting, which for the small fields is linear in field. The possibility of excitation of the modes by means of the external ac magnetic fields is discussed. To explain our numerical results for the low-frequency modes, we introduce a string model for an antiferromagnetic domain wall representing boundary of the large radius skyrmion.

I. INTRODUCTION

Antiferromagnets (AFMs) recently have become promising as active elements in spintronic devices as they have faster dynamics and are insensitive to magnetic fields; for reviews, see Refs. [1–3]. Ways to manipulate AFM textures have been predicted and experimental methods are rapidly proceeding toward imaging and controlling them [4,5]. For example, AFM domain walls have been observed and already manipulated [6]. Still, several challenges remain due to the difficulty to access directly the AFM order parameter.

Recently, AFM skyrmions have attracted a lot of attention due to their interesting properties such as the absence of a skyrmion Hall effect [7–9] and the presence of the topological spin Hall effect [9]. While these localized metastable objects were predicted several years ago [10], so far, mostly, their static properties as well as their translational motion has been studied [7,8,11–13].

II. MODEL OF AN ANTIFERROMAGNET

We consider a thin-film uniaxial collinear AFM with two magnetic sublattices $M_1$ and $M_2$ (with $|M_1| = |M_2| = M_s$), which are antiparallel and fully compensate each other in the equilibrium state. We chose the normal $\hat{z}$ of the film parallel to the magnetic easy axis, see Fig. 1. The coupling of the magnetic film to a heavy metal substrate breaks the inversion symmetry and creates an interfacial DMI whose strength $D$ can be controlled by the AFM thickness.
FIG. 1. Sketch of setup a thin film uniaxial collinear AFM with two magnetic sublattices \( M_1 \) and \( M_2 \) on top of a heavy metal substrate. Inset: Parametrization of the Néel vector in terms of spherical coordinates \( \theta \) and \( \phi \).

thickness of the AFM film is assumed to be small enough to exclude any inhomogeneities along the vertical direction. The order parameters of this AFM are given by the Néel vector \( \mathbf{n} = (M_1 - M_2)/(2M_s) \) and the magnetization \( \mathbf{m} = (M_1 + M_2)/(2M_s) \).

In the following, we will consider the case of a strong exchange field \( H_{ex} \) acting between the magnetic sublattices. It is large compared to the anisotropy field \( H_{an} \), i.e., \( H_{an}/H_{ex} \equiv \xi^2 << 1 \). In this case, the magnetization \( \mathbf{m} \) is small (i.e., \( |\mathbf{m}| \ll 1 \) and \( |\mathbf{n}| \approx 1 \)), and the state of the AFM is determined solely by the spatial and time-dependent Néel vector. The effective energy of such an AFM is given by

\[
E = L \int d^2x \left[ A(\mathbf{n} \cdot \partial \mathbf{n}) + M_s H_{an} (1 - n_z^2) + \mathcal{O}_{DMI} \right],
\]

where \( L \) is the thickness of the film, \( A \) is the exchange stiffness, and \( \mathcal{O}_{DMI} = D(n_z \mathbf{V} \cdot \mathbf{n} - n \mathbf{n} \cdot \nabla n_z) \) is the interfacial DMI, typical for AFMs of C\(_{nv}\) symmetry classes [10]. An example of material that can be described within such a model is the recently synthesized compensated Heusler compound Mn\(_2\)Ru\(_{1-x}\)Ga [17]. Note that the Einstein summation rule is used in Eq. (1).

The dynamics of the Néel vector in the presence of an external magnetic field can be effectively described within the Lagrange formalism [18–20]. The Lagrangian in rescaled parameters (see Table I) is given by

\[
\mathcal{L} = [\mathbf{n} - (\mathbf{h} \times \mathbf{n})]^2 - \mathcal{W},
\]

\[
\mathcal{W} = \partial \mathbf{n} \cdot \partial \mathbf{n} + 1 - n_z^2 + d(n_z \partial n_z - n_i \partial n_i),
\]

and is supplemented by the constraint \( |\mathbf{n}| = 1 \). Here \( d = D/\sqrt{AH_{an}M_s} \) is the DMI strength and \( \mathbf{h} = H/H_d \) represents

the rescaled magnetic field, where \( H_d = \sqrt{H_{an}H_{ex}} \) is the spin-flop field. Note that a small magnetization arises either due to the presence of a magnetic field or is induced by the dynamics of the Néel vector:

\[
\mathbf{m} = \xi [\mathbf{n} \times \mathbf{n} + \mathbf{n} \times \mathbf{h} \times \mathbf{n}].
\]

Derivation of Eq. (3) and procedure of exclusion of the magnetization from the AFM dynamics can be found in a number of previous works, see, e.g., Refs. [18,20]. The above models, Eqs. (2) and (3), are controlled by two dimensionless parameters; namely, the DMI constant \( d \) and the magnetic field \( \mathbf{h} \). The overdot indicates the derivative with respect to the dimensionless time \( \tau = t \omega_{AFMR} \), where \( \omega_{AFMR} = \gamma \sqrt{H_{an}H_{ex}} \) is the frequency of AFM resonance, \( \gamma \) is gyromagnetic ratio. Note also that the spatial derivatives are now measured with respect to the dimensionless length \( r/\ell \) where \( \ell \) is in units of the magnetic length \( \ell = \sqrt{A/(H_{an}M_s)} \) which describes the width of a plane domain wall, see Table I. The small parameter \( \xi \) can be associated with the value of the static magnetization when the applied magnetic field is equal to the spin-flop field (\( h = 1 \)) or with the dynamical magnetization when the Néel vector lying within \( xy \) plane precesses with the AFM resonance frequency, see Eq. (3). Despite that the magnetization is small in antiferromagnetic systems, we show below that it can be used for resonant excitations of some eigenmodes by means of an ac magnetic field.

In the following, we set the magnetic field parallel to the easy axis, \( \mathbf{h} = \hat{h} \mathbf{z} \). As \( |\mathbf{n}| = 1 \), we use a parametrization in spherical angular coordinates \( \mathbf{n} = \sin \theta (\cos \phi \hat{x} + \sin \phi \hat{y}) + \cos \theta \hat{z} \) leading to

\[
\mathcal{L} = \dot{\theta}^2 + (\dot{\phi} - h)^2 \sin^2 \theta - \mathcal{W}[\theta, \phi].
\]

In the next sections, we will first review the static solution of an AFM skyrmion based on which we will then derive its excitations.

### III. Static Skyrmion Solution

An AFM skyrmion is a metastable state embedded in a homogeneous collinear AFM. In a previous work [10], it has been shown that a homogeneous collinear phase with the Néel vector oriented parallel to the easy axis (\( n|\hat{z} \)) of the AFM model in Eq. (2b) requires

\[
h^2 + \delta^2 < 1 \quad \text{with} \quad \delta = \frac{\pi}{4} d.
\]

#### Table I. Units of measurement used in this paper. Typical values in the last column correspond to the Heusler compound Mn\(_2\)Ru\(_{1-x}\)Ga near its compensation point [14,15].

Here we have introduced the renormalized DMI constant $\delta$. We denote the critical value where the AFM phase and the skyrmion solution become unstable as $h_c = \sqrt{1 - \delta^2}$. As a result of instability, a modulated periodical structure (spin-flop phase) is developing if $\delta > 0$ ($\delta = 0$), see Ref. [10] for details.

### A. General equation for static AFM skyrmion

In Refs. [7,8,10,11,21], it has been shown that the system of Eqs. (2) has a static skyrmion solution. Introducing the polar frame of reference for the 2D radius-vector $\rho \equiv \rho(\cos \chi + \sin \chi \hat{y})$ within the AFM film, see Fig. 1, one obtains for the skyrmion solution $\phi = \chi + \phi_0$ and $\theta = \Theta(\rho)$, where the function $\Theta(\rho)$ is determined by the differential problem

$$
\nabla^2 \Theta - \sin \Theta \cos \Theta \left(\frac{1}{\rho^2} + 1 - h^2\right) + \frac{|d|}{\rho} \sin^2 \Theta = 0,
$$

$$
\Theta(0) = \pi, \quad \Theta(\infty) = 0.
$$

Here $\nabla^2$ is the radial part of the Laplacian and $\phi_0 = 0$ ($\phi_0 = \pi$) for positive (negative) DMI $d$. In the following, we restrict ourselves to the case $d > 0$, as $d < 0$ is completely analogous. A number of skyrmion profiles numerically obtained from Eqs. (6) are shown in Fig. 2. We define the skyrmion radius $R_0$ by the condition were the Néel vector is in plane, i.e., $\Theta(R_0) = \pi/2$.

For the case $h = 0$, Eqs. (6) coincide with the well-known equation for a ferromagnetic (FM) skyrmion [22–26] upon substitution of the Néel vector to the FM magnetization order parameter. However, in the presence of a magnetic field, i.e., $h \neq 0$, there are differences in the static solution. While in FM energy a magnetic field enters as a linear term, in the AFM it effectively diminishes the easy-axis anisotropy. In addition, the magnetic field creates a nonzero magnetization $m = \vec{m} = \xi h (\sin^2 \Theta \hat{x} - \sin \Theta \cos \Theta \hat{y})$ in the inhomogeneity region of the skyrmion, see Figs. 2(a’) and 2(c). The magnetization is localized in the vicinity of the skyrmion boundary and the $m_z$ component reaches its maximum at $R_0$.

Note that, in general, Eqs. (6) can only be solved numerically [10,11]. Therefore, in the next part, we will review the solution in the limit of large radius skyrmions.

### B. Limit of large skyrmion radius

In the limit of large radius, the skyrmion can be effectively described within a few collective variables $R_0$, $\Phi_0$ and $\Delta_0$ determining the skyrmion radius, helicity, and the domain wall (DW) width, respectively. Transferring the knowledge of FM skyrmions [27] and using that the magnetic field plays the role of an effective anisotropy in the AFM, the AFM skyrmion can be viewed as a circularly closed DW which can be described by

$$
\cos \theta(\rho) = \tanh \frac{\rho - R_0}{\Delta_0}, \quad \phi(\rho) = \chi + \Phi_0,
$$

with $\Phi_0 = 0$, and

$$
R_0 = \frac{\delta}{\sqrt{1 - h^2 \sqrt{1 - \delta^2 - h^2}}}, \quad \Delta_0 = \frac{\delta}{1 - h^2}.
$$

The DW Ansatz agrees well with the exact solution of Eqs. (6) for $R_0 \gg 1$, see Fig. 3 showing the field dependence of the...
The skyrmion radius for different DMI strengths. As expected, the skyrmion radius diverges for the magnetic field, reaching the critical value \( h_c \). Note that for \( h = 0 \), the equilibrium skyrmion radius \( R_0 \) is given by the same expression as the radius of the FM skyrmion \([22,27]\). The dependence of skyrmion radius on the DMI constant for \( h = 0 \) was studied in several previous works, see, e.g., Refs. \([10,22,27]\).

Note that the magnetic field induces a nonzero total magnetization in a skyrmion, \( \mathcal{M} = \int m \, d^2 x \), which is aligned along the field direction. In the limit of a large-radius skyrmion and a field applied along the \( z \) direction, it is \( \mathcal{M}_z = 4\pi \xi h R_0 \Delta_0 \). This means that the static magnetic susceptibility of an AFM skyrmion is proportional to the area (\( \propto 2\pi R_0 \Delta_0 \)) of the skyrmion wall.

**IV. EIGENMODES OF AN ANTIFERROMAGNETIC SKYRMION**

In this section, we formulate and solve numerically the eigenvalue problem (EVP) for an AFM skyrmion. To this end, we use a standard technique previously applied for a number of two-dimensional topological magnetic solitons, including the precessional solitons in easy-axis magnets \([28–30]\), magnetic vortices in easy-plane magnets \([31,32]\), and ferromagnetic skyrmions \([27,33,34]\). To study small excitations of AFM skyrmions, we introduce time-dependent deviations from the skyrmion solution determined by Eqs. (6),

\[
\begin{align*}
\theta &= \Theta(\rho) + \epsilon \vartheta(\rho, \chi, \tau), \\
\phi &= \chi + \varphi(\rho, \chi, \tau) / \sin \Theta(\rho),
\end{align*}
\]

where \( \epsilon \ll 1 \) and we have chosen a convenient way to accommodate for the change in the azimuthal angle \([35]\). Introducing the above ansatz into the Lagrange function \( \mathcal{L} \) of Eq. (4) leads to the expansion \( \mathcal{L} = \mathcal{L}^{(0)} + \epsilon^2 \mathcal{L}^{(2)} + \ldots \), where

\[
\begin{align*}
\mathcal{L}^{(2)} &= \delta^2 + \varphi^2 + V(\rho)(\vartheta(\rho, \phi) - \vartheta) - (\nabla \varphi)^2 \\
&\quad - U_1(\rho) \vartheta^2 - U_2(\rho) \varphi^2 + W(\rho)(\varphi \partial_\rho \vartheta - \vartheta \partial_\rho \varphi).
\end{align*}
\]

Here we introduced the potentials

\[
\begin{align*}
U_1(\rho) &= \cos 2\Theta \left( 1 + \frac{1}{\rho^2} - h^2 \right) - \frac{d}{\rho} \sin 2\Theta, \\
U_2(\rho) &= \cos^2 \Theta \left( 1 + \frac{1}{\rho^2} - h^2 \right) - \left( \partial_\rho \Theta \right)^2 \\
&\quad - \frac{d}{\rho^2} \left( \partial_\rho \Theta + \frac{\sin \Theta \cos \Theta}{\rho} \right), \\
W(\rho) &= \frac{2}{\rho^2} \cos \Theta - \frac{d}{\rho} \sin \Theta, \\
V(\rho) &= 2h \cos \Theta.
\end{align*}
\]

In the case of \( h = 0 \), the above potentials derived for the AFM skyrmion can be mapped fully to the ferromagnetic case \([27]\). For \( h \neq 0 \), there appears an additional potential \( V(\rho) \).

Next, we derive the equations of motion generated by the Lagrangian Eq. (10):

\[
\begin{align*}
\ddot{\vartheta} + V \varphi &= \nabla^2 \vartheta - U_1 \vartheta - W \partial_\rho \varphi, \\
\ddot{\varphi} - V \dot{\vartheta} &= \nabla^2 \varphi - U_2 \varphi + W \partial_\rho \varphi.
\end{align*}
\]

FIG. 4. Schematics of the perturbation (orange line) around the circular skyrmion configuration (black line) for \(|\mu| = 3\). For positive (negative) \( \mu \), the rotation is clockwise (counterclockwise).

The cyclic variable \( \chi \) in combination with the periodic boundary condition, \( [\theta(\rho, 0, \tau) = \theta(\rho, 2\pi, \tau) \text{ and } \varphi(\rho, 0, \tau) = \varphi(\rho, 2\pi, \tau) ] \), allows us to solve Eqs. (12) with the partial solutions

\[
\begin{align*}
\vartheta &= f(\rho) \cos(\omega \tau + \mu \chi + \eta), \\
\varphi &= g(\rho) \sin(\omega \tau + \mu \chi + \eta).
\end{align*}
\]

Here \( \omega \) is the frequency of the corresponding eigenmode, \( \mu \in \mathbb{Z} \) is the azimuthal quantum number, and \( \eta \) is an arbitrary phase. Superposition of all possible partial solutions Eqs. (13) composes the Fourier series of the general solution of Eqs. (12). The partial solution Eqs. (13) displays flowerlike excitations as shown in Fig. 4. The sign of \( \mu \) encodes the spatial rotation direction, \( \mu > 0 \) being clockwise (CW) and \( \mu < 0 \) being counterclockwise (CCW) with respect to the \( z \) axis. Substituting this ansatz into Eqs. (12) leads to the following EVP:

\[
\hat{\Psi} = \omega \hat{\Psi}, \quad \Psi = (f, \bar{f}, g, \bar{g})^T.
\]

FIG. 5. Schematics of the spectrum. Classification of the modes with frequency \( \omega_\mu \) according to their quantum number \( \mu \). Gray dashed lines connect the symmetry related resonances. The modes with zero frequency and \( \mu = \pm 1 \) are doubly degenerate (DD). The field-induced narrowing of the gap (between the blue zones) is not shown.
The spectrum can be divided into two equivalent subsets, with the approximation Eq. (23) of the LFB modes.

The eigenfrequencies of the modes \( \mu \geq 0 \) and \( \mu < 0 \), respectively. Thus, the modes with \( |\mu| > 4 \) are auxiliary functions.

The symmetry of the Lagrangian Eq. (10) with respect to translations along time and the \( \chi \) coordinate results in the conservation of total energy \( E = E(\mu, \omega) \) and the angular momentum \( K = K(\mu, \omega) \), respectively. For details see Appendix D.

According to Eq. (3), the excitation of a magnon mode generates a total magnetic moment in the form

\[
\hat{\mathbf{M}}_\mu = \hat{\mathbf{M}}^{(0)}_\mu + \epsilon \left[ \delta_{\mu,0} \mathbf{m}^{(1)}_\mu(\tau) + \delta_{\mu|\mu|} \mathbf{m}^{(1)}_\mu(\tau) \right] + \epsilon^2 \left[ \hat{\mathbf{M}}^{(2)}_\mu + \delta_{\mu,0} \mathbf{m}^{(2)}_\mu(\tau) \right] + \cdots ,
\]

where \( \hat{\mathbf{M}}^{(0)}_\mu = 2\pi \hbar \hat{\mathbf{z}} \int_0^\infty \rho \sin^2 \Theta \, d\rho \) is the field-induced static magnetic moment discussed in Sec. III. The time dependent parts \( \mathbf{m}^{(1)}_\mu(\tau) \) and \( \mathbf{m}^{(1)}_\mu(\tau) \) are linearly polarized along the \( \hat{\mathbf{z}} \) axis and circularly polarized within the \( xy \) plane, respectively. Thus, the modes with \( \mu = 0 \) and \( \mu = \pm 1 \) (except translational mode) can be resonantly excited by the external ac field of the corresponding polarization, see Appendix E for details. Note that the time-independent static contribution \( \hat{\mathbf{M}}^{(2)}_\mu \) does not vanish even for the case \( \mu = 0 \), see Eq. (E3).

### A. Localized modes of an antiferromagnetic skyrmion

We classify all solutions \( \Psi_{\omega_\mu} \) of the above EVP by two parameters, the frequency \( \omega \) and the azimuthal quantum number \( \mu \). Due to the combined time-reversal and space-reversal symmetry of the equilibrium solution, the eigenmodes should be invariant with respect to the operations \( \omega \to -\omega \), \( \mu \to -\mu \), \( g \to -g \) and \( f \to f \) \cite{36}, see Eqs. (14). Hence, the spectrum can be divided into two equivalent subsets, with negative and positive frequencies, respectively. The mode with zero frequency corresponds to the translational mode and will be discussed separately. This classification is shown schematically in Fig. 5. Following the previous studies, we will work with the subset of positive \( \omega \).

Our main results for the eigenmodes are shown in Figs. 6 and 7, representing the spectrum of localized modes as a function of skyrmion radius and magnetic field, respectively. We find two different types of modes which we classify as low-frequency (LFB) and high-frequency (HFB) branches. This can be best seen in Fig. 6 where all frequencies of the modes comprised in the LFB converge to zero in the large radius skyrmion limit, \( \omega_\mu \propto R_0^{-2} \), see Sec. V, while those of the HFB do not. Furthermore, Fig. 7 shows that all the modes of the LFB soften at the same condition \( h > h_{0\mu} \approx 0.06 \), see Figs. 7(a) and 7(b). In contrast to the LFB modes, the HFB modes do not soften with the skyrmion radius but converge to the finite value, see Fig. 6.

This also explains why the number of localized HFB modes increases for larger skyrmions, see Fig. 6(b). The simultaneous softening of all LFB modes is analogous to the case of the ferromagnetic skyrmion \cite{27} and can be interpreted as an essential instability associated with the possibility of a continuous (soft) transition to a new state. However, there is no analog to the HFB in the ferromagnetic case.

As the magnetic field breaks time-reversal symmetry, it induces a difference between CW and CCW rotational modes. This results in a splitting of the modes for \( |\mu| > 2 \) in the LFB and for modes \( |\mu| \geq 1 \) in the HFB, as explained in Figs. 5 and 7.

The eigenfunctions of the corresponding eigenmodes for different values of DMI and magnetic field separated in the _

\[ ^1 \text{The lower limit } \delta_{\text{ini}} \text{ is caused by technical reasons.} \]
FIG. 7. Influence of the magnetic field on spectrum of the localized modes. Field dependence of the eigenfrequencies is shown in panel (a), and HFB is detailed in panel (b). Panel (c) shows the value of splitting for the low-frequency modes $\mu = \pm 2$ and $\mu = \pm 3$, where $\Delta \omega_{\mu}^{\text{LFB}} = \omega_{\mu|} - \omega_{\mu|}$. Here $\delta = 0.9$ is fixed and $0 \leq h < h_c = \sqrt{1 - \delta^2}$. The spectrum is obtained by means of the numerical solution of EVP Eqs. (14). Note that $\mu \rightarrow -\mu$ when $h \rightarrow -h$.

HFB and LFB are shown in Fig. 8. The presented functions are normalized by the rule $1/2 \int_0^\infty \left[ f_\mu^2(\rho) + g_\mu^2(\rho) \right] d\rho = 1$. For the LFB, the amplitudes of functions $f_\mu$ are significantly larger as compared to the functions $g_\mu$ and vice versa for the case of the HFB. Also, the maxima of the functions $f_\mu$ for the LFB as well as maxima of functions $g_\mu$ for HFB correspond to position of the skyrmion boundary. This means that the modes in the LFB (HFB) address mainly the spherical angle $\theta$ ($\phi$) of the Néel vector which is associated with a position change (thickness change) of the skyrmion boundary. Note that the field induced shift of maxima of the corresponding eigenfunctions to the right reflects the effect of the skyrmion radius increase with the magnetic field, see Eqs. (8) and Fig. 3. As an additional crosscheck, we compare the numerically obtained eigenfunctions of the translational modes $f_{\pm 1}$ and $g_{\pm 1}$ with the analytically expected profiles $f_{\pm 1} = -\Theta'$ and $g_{\pm 1} = \pm \sin \Theta / \rho$, see Fig. 8 for the case of LFB.

In the following, we will discuss the specific properties of the localized modes ordered by their quantum number $\mu$.

1. Radially symmetrical modes, $\mu = 0$

The localized modes with $\mu = 0$ do not break the space inversion symmetry, see Fig. 8, first column. As such, they respect the symmetry of the equilibrium solution of the skyrmion. Furthermore, an applied magnetic field does not couple to their dynamical degrees of freedom, see Fig. 7, but just changes the static solution of the skyrmion which can be translated to an effective anisotropy change. This explains that an increase in magnetic field leads to a reduction of their frequencies, see Figs. 6 and 7.

FIG. 8. Examples of eigenfunctions of localized eigenmodes for $|\mu| \leq 2$. The upper and lower rows correspond to HFB and LFB, respectively. The presented eigenfunctions and eigenfrequencies are obtained by means of numerical solution of EVP Eqs. (14). The vertical lines indicate the skyrmion radius $\rho = R_0$. The thin yellow lines shown for modes $\mu = \pm 1$ of LFB correspond to the eigenfunctions of the translational modes $f_{\pm 1}$ and $g_{\pm 1}$ when the normalization is applied. Note that in the absence of the field, $f_0 \equiv 0$ for the HFB (the in-plane component is only excited) and $g_0 \equiv 0$ for the LFB (the out-of-plane component is only excited). However, both in-plane and out-of-plane components are excited for modes with $|\mu| > 0$ or in presence of a field.
The LFB localized mode is called breathing mode [37] and corresponds to dynamics of the out-of-plane components of the Néel vector. It describes a dynamical contraction and expansion of the skyrmion area with the frequency $\omega_0^{\text{LFB}} \approx 1/R_c^2 - h^2/\delta$ (see Appendix C).

The HFB mode corresponds to an in-plane oscillation of the Néel vector parameterized by the spherical angle $\phi$. Furthermore, this mode has a total nonzero dynamic magnetization $m_0^{(1)}(\tau) \propto \xi \omega_0 \cos(\omega_0 \tau + \eta_0) \hat{z}$ originated in the solidlike rotation of the skyrmion boundary (see Appendix E for the details). Therefore, this mode couples to the perpendicular ac magnetic field and can be excited resonantly, similar to breathing modes in a ferromagnetic skyrmion [37]. For the case $h = 0$, the LFB breathing mode does not generate the total dynamical moment, see Eq. (15) and Appendix E. However, in the presence of a static magnetic field which naturally intermixes rotations and radius oscillations, the antiferromagnetic LFB breathing mode can be excited in a similar way.

Note, that decoupling of out-of-plane (LFB mode) and in-plane (HFB mode) oscillations of the Néel vector in absence of the magnetic field is a particular feature of an AFM skyrmion. In ferromagnetic skyrmions, dynamics of the in-plane and out-of-plane components of magnetization are always coupled while the magnetization precesses around the in-plane and out-of-plane components of magnetization are always coupled while the magnetization precesses around the effective field.

2. Gyrotropic modes, $\mu = \pm 1$

There are four localized modes with $|\mu| = 1$, where each two of them belong to the LFB and HFB, respectively. The modes $\mu = \pm 1$ in the LFB are translational zero modes $\omega_{\pm 1} = 0$ [38] with the corresponding eigenfunctions $f_{\pm 1} = -\delta_\rho \Theta$ and $g_{\pm 1} = \pm \sin \Theta / \rho$. These modes are not affected by a magnetic field as its excitation does not break the translational invariance. In contrast to the ferromagnetic skyrmion [27,39], an AFM skyrmion has two translational modes which correspond to two independent degrees of freedom related to the motion of the skyrmion center. In analogy to light, where two linearly polarized beams can be used to create circular polarized light, these two modes can be combined to CW and CCW gyrotropic modes with zero frequency, see Fig. 9. The translational modes do not create a dynamic magnetization (see Appendix E).

The modes in the HFB with $\omega_{\pm 1} \neq 0$ are different gyrotropic modes where the skyrmion wall width oscillates, see Fig. 9. This is reflected by the fact that the in-plane $g$ component is more intensive than the out-of-plane $f$ component, which has a node in vicinity of the skyrmion radius, see Fig. 8. This also means that the degeneracy is lifted by a magnetic field, Figs. 6 and 7. In contrast to the translational modes, the HFB counterparts generate magnetic moment $m_1^{(1)}(\tau)$ even in absence of the external magnetic field. The moment $m_1^{(1)}$ uniformly rotates within the $xy$ plane, see Eq. (E2). So, this mode can be resonantly excited by the circularly polarized ac magnetic field.

3. Higher modes, $|\mu| \geq 2$

For $|\mu| \geq 2$, the modes appear below the continuum only when the skyrmion radius exceeds a certain $\mu$-dependent threshold. The LFB modes resemble the flowerlike modes similar to the FM case. [27,28,40–42] The HFB modes are related with skyrmion wall width changes. All the modes split due to a magnetic field. For the LFB, the value of the field-induced frequency splitting is nonmonotonic in field, has a maximum for $0 < h < h_c$, and vanishes when the magnetic field approaches the critical field, $h \to h_c$, see Fig. 7(c). This can be understood intuitively as follows. An increase of the field leads to a reduction in the anisotropy, thereby increasing the skyrmion radius. When approaching the critical field, the skyrmion radius diverges, see Fig. 3. In this case, the central part of the skyrmion resembles an AFM with vanishing magnetization and effective anisotropy. This effectively restores the time-reversal invariance and the degeneracy of the two modes. Note, that the modes with $|\mu| \geq 2$ cannot be excited by spatially homogeneous fields.

In the following section, we will explain our results within an intuitive analytical model.

V. SIMPLE MODEL OF THE ANTIFERROMAGNETIC DOMAIN WALL STRING

The aim of this section is to obtain an analytical estimation for the eigenfrequencies. We focus on the LFB modes and consider the limit $R_0 \gg 1$. In this case, the AFM skyrmion can be considered as a circularly closed AFM domain wall. Since
the field influence on the LFB modes vanishes for the large-radius skyrmions, see Fig. 6(a), we restrict the discussion to the field-free case. For the modes in the LFB we observe that the main effect of the excitation is to modify the shape of the skyrmion boundary. As the excitations are localized sharply on the skyrmion boundary (see Fig. 8) and leave the skyrmion wall width almost unchanged [see Figs. 9(a) and 9(c)]; in the following, we will treat the skyrmion eigenmode dynamics in terms of an effective string model accounting only for the position of the skyrmion boundary and its curvature. Recently, the analogous formalism was developed for ferromagnetic domain walls [43,44] and it was applied for the description of large radius skyrmion eigenmodes. Here the skyrmion boundary was treated as a curve or string representing the effective coordinate of the system.

A. Curvilinear Lagrange formalism for antiferromagnetic Néel domain walls

Here we consider a 2D antiferromagnetic DW, whose center position can be described by a curve $\mathbf{R}(u, \tau) = \hat{x}(u, \tau) + \hat{y}R(u, \tau)$, where $u$ is the time-independent parameter of the curve and $\tau$ describes a potential time dependence, see Fig. 4. Along the curve $\mathbf{R}$, one can introduce a local orthonormal basis,

$$
e_{\gamma}(u, \tau) = \frac{\partial \mathbf{R}}{\partial \gamma}, \quad e_{\nu}(u, \tau) = \frac{\partial \mathbf{R}}{\partial \nu},$$

where prime denotes the derivative with respect to $u$. The vectors $e_{\gamma}$, $e_{\nu}$ and $\hat{z}$ are the tangential, normal and binormal vectors for the Frenet-Serret basis of the curve, respectively [45]. In vicinity of the curve $\mathbf{R}$, the position of any point $(x, y)$ can be determined by a pair of local curvilinear coordinates $(u, \nu)$, which are defined as a solution of the following vector equation,

$$
r = \mathbf{R}(u, \tau) + v e_{\nu}(u, \tau),$$

where $r = x\hat{x} + y\hat{y}$. Note, that due to the explicit time dependence of the vectors $\mathbf{R}$ and $e_{\nu}$, the curvilinear coordinates $(u, \nu)$ are time dependent [46]. In formal terms, we require $|\nu| \ll 1$, where $\nu = z \cdot |\partial \mathbf{R}/\partial \nu|^2/|\partial \mathbf{R}|^3$ is the curvature of $\mathbf{R}$. This representation allows us to parametrize the Néel vector at any point in the vicinity of the curve $\mathbf{R}$.

Motivated by the LFB eigenfunctions (shown in Fig. 8), where the dominant contribution of the skyrmion excitation is related with the angle $\theta$ (described by $f_{\mu}$), we restrict ourselves to the following Néel wall ansatz [47]:

$$
n = \cos \Theta \hat{z} - \sin \Theta e_{\nu},$$

$$
\cos \Theta = -\tanh \frac{\nu(\tau)}{\Delta}.
$$

The action for our system is given by

$$
\mathcal{S} = \int dt \int dS \mathcal{L} = 2 \int dt \int dv \mathcal{L}^{\text{eff}},
$$

where the Lagrange function $\mathcal{L}$ is given by Eqs. (2) and $dS = |\partial \mathbf{R}/\partial \nu| |1 - \nu\mathbf{\nu}| dv/\nu$ is the infinitesimal area element in curvilinear coordinates. After substituting our ansatz [Eqs. (18)] into the Lagrangian and integrating out the normal coordinate $\nu$, we obtain the effective Lagrangian $\mathcal{L}^{\text{eff}}$ for the domain-wall string, for details see Appendix A:

$$
\mathcal{L}^{\text{eff}} = \mathcal{L}^{\text{eff}} - \mathcal{L}^{\text{eff}},
$$

$$
\mathcal{L}^{\text{eff}} = \frac{|\mathbf{R} \times \mathbf{\nu}|^2}{\Delta |\mathbf{\nu}|} + \frac{\Delta [\mathbf{R} \times \mathbf{\nu}]^2}{|\mathbf{\nu}|^3},
$$

$$
\mathcal{L}^{\text{eff}} = \frac{|\mathbf{R}|}{\Delta} [1 - 2\delta \Delta + \Delta^2 (1 + \nu^2) + \mathcal{O}(\Delta^4 \Delta^4)].
$$

The effective Lagrangian is a sum of a pure kinetic term $\mathcal{L}^{\text{eff}}$ and the potential energy of the domain wall $\mathcal{L}^{\text{eff}}$ originating from the different contributions in Eq. (4). This Lagrange formalism provides the basis for the description of the slow dynamics of the AFM Néel domain walls and skyrmions with small curvatures. In the next subsection, we will apply it to the particular case of small excitations of circular AFM skyrmions. For further illustration of the formalism, we discuss the simplest example, i.e., the one of an AFM domain wall in Appendix B.

B. Circular AFM skyrmion

In general, a large radius skyrmion can be represented as a circular domain wall $\mathbf{R} = R(\hat{x} \cos \Phi + \hat{y} \sin \Phi)$, where the angle $\Phi$ is the parameter of the curve ($0 \leq \Phi \leq 2\pi$) and $R$ is the radius of the skyrmion. For the model of Eqs. (20), the static equilibrium solution is given by $R_0 = \delta/\sqrt{T - \Delta^2}$, and $\Delta_0 = \delta$, which corresponds to the circular DW coinciding with our previous results, Eqs. (8). To describe excitations, we introduce a small deviation from the static solution, $R = R_0 + r(u, \tau)$ and $\hat{F} = u + \psi(u, \tau)$. With this, one can derive the harmonic part of the effective Lagrangian Eqs. (20) as follows:

$$
\mathcal{L}^{\text{eff}} \approx R_0^2 (R_0^2 + 1) \dot{\nu}^2 + R_0^2 (R_0 \dot{\psi} - \dot{r})^2
$$

$$
- r^\circ /2 + 2r^\circ /2 - \nu^2.
$$

As the effective Lagrangian does not depend explicitly on $\psi$ (cyclic variable), the time-independent quantity $\dot{F} = R_0 \dot{\psi} - \dot{r}$ is conserved. $\dot{F}$ plays the role of an orbital momentum corresponding to a rigid rotation of the system and can be set to be zero in the inertial frame. Thus, we obtain the Euler-Lagrange equation for the radius:

$$
R_0^2 (R_0^2 + 1) \ddot{\nu} + r(0) + 2R_0^2 + r = 0.
$$

The latter has solutions in the form of azimuthal waves, $r(u, \tau) = r_0 \cos(\omega_\mu \tau + \mu u + \eta)$ with dispersion

$$
\omega_\mu = \frac{1 - \mu^2}{R_0 \sqrt{R_0^2 + 1}} \approx \frac{1 - \mu^2}{R_0^2}.
$$

For the deviation of the angle, we then find $\psi(u, \tau) = \psi_0 \sin(\omega_\mu \tau + \mu u + \eta)$, where $\psi_0 = -\epsilon_0 \mu / R_0$. For the breathing mode $\mu = 0$, the amplitude $\psi_0 = 0$ of the in-plane oscillations vanishes. This is in a full agreement with the numerical results shown in Fig. 8 and with the analytical prediction Eq. (C3). Note that Eq. (23) also correctly describes the translational modes with $\mu = \pm 1$ and $\omega_\mu = 0$.

The asymptotic solutions of $\omega_\mu$ presented by Eq. (23) are shown in Fig. 6(a) by thin solid black lines.
VI. CONCLUSIONS

We demonstrated that the AFM skyrmion has a discrete spectrum of bound eigenstates. The properties of these states were studied both analytically and numerically. The spectrum consists of two branches. The modes of the LFB demonstrate a significant dependence on the skyrmion radius, see Eq. (23), and they are responsible for the skyrmion instability when the DMI strength exceeds some critical value. The modes of the HFB are compactly situated at the magnon continuum and they are not involved in the instability process. All the modes, except the radially symmetrical one, are doubly degenerated with respect to the sense of rotation around the skyrmion center: clockwise or counterclockwise. An out-of-plane magnetic field removes the degeneracy (for all modes except translational), resulting in a frequency splitting, which for the small fields is linear in field. For the large-radius skyrmion, the low-frequency modes can be interpreted as oscillations of a circularly closed AFM domain wall (geometric degree of freedom). The high-frequency modes correspond to oscillations of the magnetic deviations from the domain-wall structure (magnetic degree of freedom). The external magnetic field mixes the geometrical and magnetic degrees of freedom. The high-frequency modes with $\mu = 0$ and $\mu = \pm 1$ can be excited by the ac magnetic field which is linearly polarized along the $z$ axis or circularly polarized within the $xy$ plane, respectively. The low-frequency breathing mode ($\mu = 0$) can be excited by the perpendicular ac field only in the presence of an external bias field along the $z$ axis. The translational modes cannot be excited by the magnetic fields.

In addition to our numerical study, we have developed a formalism to describe extended AFM domain walls in terms of a collective string dynamics. Applying our theory to AFM skyrmion interpreted as circular AFM domain walls, we analytically predict the asymptotic for the low-frequency part of the AFM skyrmion spectrum. Overall, our study of the AFM skyrmion excitations provides guidance for experiments to detect them. For example, we expect that, in particular, for large-radius skyrmions the low-energy excitations can be observed by Brillouin light scattering techniques.

APPENDIX A: DETAILS OF THE DW STRING MODEL

In this Appendix, we show how to derive the effective Lagrangian $\mathcal{L}_{\text{eff}}$ in Eq. (19) of the main text

$$\mathcal{L}_{\text{eff}} = \frac{|\mathbf{R}|}{2} \int (1 - \kappa v) d\mathbf{v} = \mathcal{F}_{\text{eff}} - \varepsilon_{\text{eff}}, \quad (A1a)$$

where the kinetic and potential energy parts using Eqs. (2) are given by

$$\mathcal{F}_{\text{eff}} = \frac{|\mathbf{R}|}{2} \int (1 - \kappa v) n^2 d\mathbf{v}, \quad (A2a)$$

$$\varepsilon_{\text{eff}} = \frac{|\mathbf{R}|}{2} \int (1 - \kappa v) \mathcal{W} d\mathbf{v}. \quad (A2b)$$

Let us compute now the effective kinetic energy $\mathcal{F}_{\text{eff}}$. For the ansatz of Eqs. (18), we obtain $n^2 = \hat{\Theta}^2 + \sin^2 \Theta e^2_\perp$ with $\hat{\Theta} = \text{sech}(v/\Delta)\sqrt{v/\Delta}$. Taking into account that the time derivative of a coordinate vector $\mathbf{r}$ is zero, we differentiate Eq. (17) by time and solve the obtained set of equations with respect to $\hat{v}$ and $\hat{u}$. This results in $\hat{v} = \frac{\dot{z}}{|[\mathbf{R} \times \hat{\mathbf{R}}]/|\mathbf{R}||}$, where the $\mathbf{R} = \partial \mathbf{R}/\partial \tau$ is the time derivative with respect to the explicit time dependence. With this we obtain

$$\hat{\Theta} = \frac{\dot{z}}{|\mathbf{R}|} \frac{[\mathbf{R} \times \hat{\mathbf{R}}]}{\Delta |\mathbf{R}|} \text{sech} \left( \frac{v}{\Delta} \right). \quad (A3)$$

Using the definition of the basis vectors, Eqs. (16), one obtains

$$e^2_\perp = e^2_\parallel = \frac{|\mathbf{R} \times \hat{\mathbf{R}}|^2}{|\mathbf{R}|^4}. \quad (A4)$$

By integrating Eq. (A2a) we derive the effective kinetic energy of the domain-wall string, Eq. (20b).

For the derivation of the effective potential energy of the domain wall $\varepsilon_{\text{eff}}$, we need to calculate the defined in Eq. (2b) energy density $\mathcal{W} = \mathcal{W}_\text{ex} + \mathcal{W}_\text{an} + \mathcal{W}_\text{DMI}$ for the case of ansatz Eqs. (18) formulated in the curvilinear coordinates $(u, v)$. While the anisotropic contribution is trivial $\mathcal{W}_\text{an} = \sin^2 \Theta$, the calculation of the exchange $\mathcal{W}_\text{ex} = (\nabla \Theta)^2 + \mathcal{O}^2 \sin^2 \Theta$ and DMI $\mathcal{W}_\text{DMI} = -2\sin^2 \Theta (e_\parallel \cdot \nabla \Theta)$ terms requires the technique previously developed for the curvilinear systems [48,49]. Here $\nabla = e_\perp |\mathbf{R}|^{-1} (1 - \kappa v)^{-1} \partial_u + e_\parallel \partial_v$ is the surface gradient and $\mathcal{O} = -|e_\perp (1 - \kappa v)^{-1} e_\parallel|$ is the vector of spin connection [50,51]. The usage of the mentioned techniques requires the metric tensor $|\mathbf{g}_{\alpha\beta}| = \text{diag}(|\mathbf{R}|^2 (1 - \kappa v)^2, 1)$, which can be straightforwardly obtained from the parametrization Eq. (17) with the application of the Frenet-Serret formulas $e_\parallel = |\mathbf{R}| e_\parallel$ and $e_\parallel = -|\mathbf{R}| e_\parallel$, the area element reads $dS = \sqrt{\mathbf{g}} dudv$.

Integrating now Eq. (A2b) leads to the effective potential energy for the domain-wall string in the form of Eq. (20c).
APPENDIX B: DOMAIN-WALL STRING

In this section, we consider the model of Eqs. (2) and illustrate the application of the string model to excitations of a planar antiferromagnetic DW, which is described by the equilibrium solution \( \mathbf{R}_0 = u \hat{x} \) and \( \Delta_0 = 1 \). Let us introduce small deviations \( \mathbf{R} = \mathbf{R}_0 + x \hat{x} + y(u, t) \hat{y} \), where \( |x|, |y| \ll 1 \). In harmonic approximation with respect to the deviations \( x \) and \( y \), the Lagrangian in Eqs. (20) is given by
\[
\mathcal{L}^{\text{eff}} \approx \dot{y}^2 + \dot{y}''^2 - (1 - \delta) \phi^2. \tag{B1}
\]
The corresponding equation of motion
\[
\ddot{y} - \dot{y}'' - (1 - \delta) \phi'' + \phi^0(y) = 0 \tag{B2}
\]
has a plane-wave solution \( y(u, \tau) \propto \cos(q u - \omega \tau + \eta) \) with the spin–wave spectrum
\[
\omega = |q| \sqrt{1 - \delta}. \tag{B3}
\]
where \( q \) is the wave vector along the DW. This linear dispersion relation coincides with the results found in Ref. [52]. In contrast to oscillations of a ferromagnetic DW [40,43], the excitations of the antiferromagnetic DWs in the LFB do not show a nonreciprocity effect, even in the presence of DMI (opposite directions \( LFB \) do not show a nonreciprocity effect, even in the presence of DMI).

APPENDIX C: MODES WITH \( \mu = 0 \) IN LARGE SKYRMION LIMIT

In this section, we derive approximate expressions for both LFB and HFB with \( \mu = 0 \) in presence of the magnetic field, whose asymptotics is not fully covered with the string model. As in the field absence, the modes with \( \mu = 0 \) keep the symmetry of equilibrium skyrmion solution, they can be approximately described with the same ansatz Eqs. (7) as equilibrium skyrmion:
\[
\cos \theta(\rho, \tau) = \frac{\rho - R(\tau)}{\Delta}, \quad \phi(\rho, \tau) = \chi + \Phi(\tau), \tag{C1}
\]
where \( \Delta \) is the domain wall width.

In the absence of a magnetic field, a LHB (HFB) mode with \( \mu = 0 \) corresponds to pure out-of-plane (in-plane) oscillations of the Néel vector seen as the radial (tangential) oscillations of the DW.

The dynamics of the collective variables is determined by the effective Lagrange function,
\[
\mathcal{L}^{\text{eff}} = \frac{R^4}{\Delta} + \Delta R(\dot{\Phi} - h) - \frac{R}{\Delta} - \Delta R + 2 \delta R \cos \Phi, \tag{C2}
\]
where we neglect possible explicit time dependence of \( \Delta \).

Using symmetry arguments, we represent the collective variables as \( \Phi = \Phi_0 + \psi(\tau), R = R_0 + r(\tau) \), where \( \psi(\tau) \) and \( r(\tau) \) are small excitations of equilibrium soliton solution with the parameters \( \Phi_0 \) and \( R_0 \) given by Eqs. (8). Linearized equations of motion for excitations are then obtained from the Lagrange function Eq. (C2) as
\[
\ddot{r} + \omega_L^2 r + h \frac{\Delta_0^2}{R_0} \psi = 0, \tag{C3a}
\]
\[
\ddot{\psi} + \omega_H^2 \psi - \frac{h}{R_0} \dot{r} = 0, \tag{C3b}
\]
where \( \omega_L = \Delta_0/R_0^2 \) and \( \omega_H = \sqrt{\delta/\Delta_0} \).

APPENDIX D: INTEGRALS OF MOTION

The Lagrange function in Eq. (10) does not explicitly depend on spatial azimuthal angle \( \chi \) and time. This leads to two integrals of motion. The first is associated to the rotation invariance along the \( z \) axis and corresponds to the angular momentum \( K = \int \rho \times \mathbf{P} d^2 x \). Here \( \mathbf{P} = e_x \rho^{-1} (2 \delta \dot{\varphi} \dot{\varphi} + \dot{\psi} \dot{\chi} - \dot{\psi} \dot{\varphi}) \) is density of the linear momentum corresponding to the translations along \( \chi \). In terms of the partial solutions Eqs. (13), one obtains
\[
K = 2 \pi \mu z \int_0^\infty \rho [\omega (f^2 + g^2) - V f d] d \rho. \tag{D1}
\]
It is linear in the azimuthal quantum number \( \mu \). The second integral of motion is the total energy \( E = \int \rho d^2 x \), where \( E = \delta^2 + \varphi^2 + (V \varphi)^2 + \chi^2 + U_1 \varphi^2 + U_2 \varphi^2 + W (\varphi \delta \varphi \varphi - \varphi \delta \psi) \). Substitution with the partial solutions Eqs. (13) provides
\[
E = \pi \int_0^\infty \rho \omega (f^2 + g^2) + f^2 + g^2 + 2 \mu W f g + \left( \frac{\mu^2}{\rho^2} + U_1 \right) f^2 + \left( \frac{\mu^2}{\rho^2} + U_2 \right) g^2 d \rho. \tag{D2}
\]
As it follows from Eqs. (D1) and (D2), both integrals of motion depend on the two parameters \( K = K(\mu, \omega) \) and \( E = E(\mu, \omega) \). Note that for the translational modes \( K(\pm 1, 0) = 0 \) and \( E(\pm 1, 0) = 0 \). This can be straightforwardly derived from Eqs. (D1) and (D2) when the explicit form of the eigenfunctions is substituted. For the energy calculation, it is instructive to utilize Eqs. (14).

APPENDIX E: DYNAMICAL MAGNETIC MOMENT

Applying Eqs. (9) and (13) to Eq. (3) and integrating over the film area one straightforwardly obtains Eq. (15), where
\[
\mathbf{m}_x^{(1)}(\tau) = \xi (\omega_0 \delta \omega^0 + h \delta h^0) \cos(\omega_0 \tau + \eta_0) x, \tag{E1}
\]
with \( \omega^0 = -2 \pi \int_0^\infty \rho g_0 \sin \Theta \ d \rho \) and \( \delta h^0 = 2 \pi \int_0^\infty \rho f_0 \sin 2 \Theta \ d \rho \). Note that for the LFB, one has \( \delta h^0 = 0 \) if \( h = 0 \).
This is because \( g_0 = 0 \) for this case, see Fig. 8. Thus, in the absence of a static field, \( m_0^{(1)} = 0 \) for the LFB and the corresponding breathing mode can not be excited by the external field,

\[
m^{(1)}_0(\tau) = \tilde{\xi}(\omega_1^{±1} R^{(1)}_1 + h R^{(2)}_1)[\cos(\omega_1^{±1} \tau + \eta_1^{±1}) \hat{x} + \sin(\omega_1^{±1} \tau + \eta_1^{±1}) \hat{y}],
\]

where \( R^{(1)}_1 = \int_0^{\infty} \rho(\tau, \theta) d\rho \) and \( R^{(2)}_1 = \int_0^{\infty} \rho(\tau, \theta) d\rho \). Thus, the gyrotropic modes can be excited by the in-plane ac field of the circular polarization. However, such a field cannot induce the skyrmion motion, because for the translational modes \( \omega_1^{±1} = 0 \) and \( R^{(2)}_1 = 0 \). The modes with \( |\mu| \geq 2 \) do not contribute to the linear (in \( \epsilon \)) part of the total magnetic moment.

For any \( \mu \), there appears the static magnon induced contribution,

\[
\mathcal{M}^{(2)}_\mu = \pi \tilde{\xi} \int_0^{\infty} \rho[hf_\mu^2 \cos(2\theta) - 2\omega_\mu f_\mu g_\mu \cos \theta] d\rho,
\]

which survives also for the case \( h = 0 \). If \( \mu = 0 \), then the quadratic (in \( \epsilon \)) part of the total moment gains the time-dependent part \( m^{(1)}_0(\tau) = M^{(2)}_\mu^0 \cos(2\omega_\mu \tau + 2\eta_\mu) \) with the doubled frequency.

[16] The exchange interaction which keeps the magnetization vectors on the different sublattices antiparallel, is parametrized by the value of the \( H_{ex} = 2/M_\mu \), where \( M_\mu \) is the constant of the uniform exchange energy with density \( \mathcal{E}^{ex} = 2M_\mu^2 \).

[35] In a local rotating frame of reference \([e_1, e_2, n_0]\), where \(n_0\) is the equilibrium direction of the Néel vector and \(e_1 \times e_2 = n_0\), deviations \(\vartheta\) and \(\varphi\) introduced in Eq. (9) have a sense of projections of the vector \(n\) on the transversal directions \(e_1\) and \(e_2\) [53,54], and therefore they have the same order of smallness.

[36] Or, alternatively, \(\omega \rightarrow -\omega\), \(\mu \rightarrow -\mu\), \(g \rightarrow g\) and \(f \rightarrow -f\).

[46] Note there is difference between \(u\) and \(\mu\): \(u\) is time-independent parameter of the curve, while \(\mu\) is a time-dependent coordinate of a point in the \(xy\) plane.

[47] For a circularly closed DW, the normal vector \(e_n\) is oriented inward as it is used in curvilinear approaches. Therefore, the sign \(\sim -\) appears in Eqs. (18).
